Abstract Algebra and Type Classes

Principles of Functional Programming

Doing Abstract Algebra with Type Classes

Type classes let one define concepts that are quite abstract, and that can be instantiated with many types. For instance:

```scala
trait SemiGroup[T]:
  extension (x: T) def combine (y: T): T
```

This models the algebraic concept of a semigroup with an associative operator `combine`.

Doing Abstract Algebra with Type Classes

Type classes let one define concepts that are quite abstract, and that can be instantiated with many types. For instance:

```
trait SemiGroup[T]:
  extension (x: T) def combine (y: T): T
```

This models the algebraic concept of a semigroup with an associative operator `combine`.

We can then define methods that work for all semigroups. For instance:

```
def reduce[T: SemiGroup](xs: List[T]): T =
  xs.reduceLeft(_.combine(_))
```

Type Class Hierarchies

Algebraic type classes often form natural hierarchies. For instance, a
monoid is defined as a semigroup with a left and right unit element.

Here's its natural definition:

```scala
trait Monoid[T] extends SemiGroup[T]:
  def unit: T
```

Exercise

Generalize `reduce` to work on lists of `T` where `T` has a `Monoid` instance such that it also works for empty lists.

Exercise

Generalize reduce to work on lists of T where T has a Monoid instance such that it also works for empty lists.

```
def reduce[T](xs: List[T])(using m: Monoid[T]): T =
  xs.foldLeft(m.unit)(_.combine(_))
```

Using Context Bounds

In the previous example we had to pass an explicitly named type class instance m: Monoid[T] to reduce, so that we could refer to m.unit.

One could alternatively use a context bound and a summon.

```
def reduce[T: Monoid](xs: List[T]): T =
  xs.reduceLeft(summon[Monoid[T]].unit)(_.combine(_))
```

Streamlining Access

A simpler calling syntax can we obtained if we do some preparation in the
Monoid trait itself.

```
trait Monoid[T] extends SemiGroup[T]:
  def unit: T
object Monoid:
  def unit[T](using m: Monoid[T]) = m.unit
```

This defines a global function Monoid.unit[T] that returns the unit of the
Monoid[T] instance that is currently visible.

With this helper, reduce can be written like this:

```
def reduce[T: Monoid](xs: List[T]): T =
  xs.reduceLeft(Monoid.unit[T])(_.combine(_))
```

Multiple Typeclass Instances

It's possible to have several given instances for a typeclass/type pair. For instance, `Int` could be a `Monoid` in (at least) two ways:

- ▶ with + as combine and 0 as unit, or
- ▶ with * as combine and 1 as unit.

```scala
given sumMonoid as Monoid[Int]:
  extension (x: Int) def combine(y: Int) : Int = x + y
  def unit: Int = 0

given prodMonoid as Monoid[Int]:
  extension (x: Int) def combine(y: Int) : Int = x * y
  def unit: Int = 1
```

Exercise

Define the sum and product functions on List[Int] in terms of reduce.

Exercise

Define the sum and product functions on List[Int] in terms of reduce.

```
def sum(xs: List[Int]): Int = reduce(xs)(using sumMonoid)
def product(xs: List[Int]): Int = reduce(xs)(using prodMonoid)
```

What happens if you leave out the using arguments?

Exercise

Define the sum and product functions on List[Int] in terms of reduce.

```
def sum(xs: List[Int]): Int = reduce(xs)(using sumMonoid)
def product(xs: List[Int]): Int = reduce(xs)(using prodMonoid)
```

What happens if you leave out the using arguments?

An ambiguity error.

Typeclass Laws

Algebraic type classes are not just defined by their type signatures but also by the laws that hold for them.

For example, any given instance of `Monoid[T]` should satisfy the laws:

```
x.combine(y).combine(z)  ==  x.combine(y.combine(z))
       unit.combine(x)   ==  x
       x.combine(unit)   ==  x
```

where `x`, `y`, `z` are arbitrary values of type `T` and `unit = Monoid.unit[T]`.

The laws can be verified either by a formal or informal proof, or by testing them.

A good way to test that an instance is *lawful* is using randomized testing with a tool like ScalaCheck.
